Thermodynamic Methods for the Study of Interfacial Regions in Electrochemical Systems

ROGER PARSONS

1. Introduction

Thermodynamics is concerned with the relations between the observable properties of macroscopic pieces of matter. It is essentially an empirical science based on accumulated experience of the behavior of real systems. Its great utility is due to the fact that it enables information derived from experiment to be presented in a form which may be more readily understandable than the experimental results themselves. This transformation of information may be done without a detailed knowledge of the structure of the system being studied. Conversely, if no information about structure is contained in the original experimental data, no such information can be obtained by the operation of thermodynamic transformations on these data.

This chapter is concerned with the deduction of information about the composition of interfacial regions from a property such as the interfacial tension in a liquid system together with a knowledge of the equilibrium properties of the adjoining bulk phases. This particular transformation of information may be claimed as the most remarkable of the applications of classical thermodynamics. The technique by which this may be carried out was developed

2 ROGER PARSONS

first by Gibbs⁽¹⁾ in 1878 in his comprehensive paper "On the Equilibrium of Heterogeneous Substances." He used the device of representing the real system (which consists of two bulk phases with an *interphase* between them) by an equivalent system in which the properties of the adjoining phases remain constant up to a mathematical plane, the interface, separating them. All differences of properties between the real system and this model system were then ascribed to the interface. This approach is often considered to be too abstract and certainly runs into difficulties when the interphase is curved or not at equilibrium. (2) Nevertheless, for a plane interphase, at equilibrium, the deductions from the Gibbs model are identical with those made from a model using an interfacial region of finite thickness, (3,4) and there is good reason to believe that they are completely correct. Gibbs' method was devised with great ingenuity at a time when little was known about the real thickness of interfacial regions and it is independent of this knowledge. However, the finite interphase method is probably easier to understand, as well as being capable of wider application; consequently this approach will be used in the present chapter.

The use of a model having an interphase of finite thickness also has advantages in the discussion of systems containing charged particles because of the long-range character of electrostatic forces. The region of inhomogeneity in such systems thus tends to be of greater extent than in the absence of particles carrying a net electric charge. It is possible for these inhomogeneous regions to become macroscopic, if the phases are poor conductors or if macroscopic pieces of matter carry finite charge. Under the latter condition the forces between pieces of charged matter become very large indeed, as illustrated dramatically by Feynman. (5) It is unusual to carry out electrochemical experiments using pieces of matter which bear a net charge, partly because large energies are required to create these charges. Consequently, it will be assumed here that there is no macroscopic separation of charge, although of course there is often free movement of charge within a phase as well as across an interphase.

Although Gibbs provided the basic foundation for the thermodynamic interpretation of interfacial phenomena, the application of his principles to charged interfaces has been the subject of much discussion in particular situations. In fact, the equation summarizing the most important characteristic of an electrochemical interphase was derived by Lippmann⁽⁶⁾ even before Gibbs' work was published [Eq. (3.72)]. His derivation assumed that no charge transfer across the interface occurs; this situation has come to be known as an *ideal polarized* or *blocked* interface. The distinction between the ideal polarized interface and other types of interface, across which charge transfer can occur, has led to some controversy as to whether there is a difference in kind, or merely a difference in degree. In fact, the different points of view lead to the same practical results; an illustration of the lack of dependence of thermodynamics on the model adopted. Frumkin⁽⁷⁾ seems to have been the first to show clearly that the ideal polarized interface is a limiting case of the interface with charge transfer. Later, Grahame⁽⁸⁾ showed, in an illustrative and quantitative way, the reasons for the

existence of this limiting case, although in his thermodynamic analysis⁽⁹⁾ he followed to a large extent the work of Koenig, ⁽¹⁰⁾ who assumed the existence of a physical barrier to charge transfer.

The reasons for the absence of finite charge transfer may be illustrated by considering, as an example, mercury in contact with aqueous KCl. The possible reactions which would transfer charge across the interphase are

$$Hg \rightleftharpoons \frac{1}{2}Hg_2^{2+} + e$$
 (1.1)

$$K(Hg) \rightleftharpoons K^+ + e$$
 (1.2)

$$Cl^{-} \rightleftharpoons \frac{1}{2}Cl_{2} + e \tag{1.3}$$

$$\frac{1}{2}H_2 + OH \stackrel{\sim}{=} H_2O + e \tag{1.4}$$

each reaction being written in the standard way with the electron on the righthand side. From the Nernst equation and the known standard electrode potentials, it is possible to calculate the concentration of the minority component in each couple at any given electrode potential. This has been done in Table I for two potentials, -0.2 and 0.8 V, with respect to the hydrogen electrode potential; the activities of Hg, KCl, and H₂O were assumed to be unity for each reaction. From these results it is then possible to find the charge required to change the concentration of the minority species from its equilibrium value at -0.2 V to the equilibrium value at -0.8 V if an assumption is made about the volume of the bulk phases. Here it is assumed that the volume of each bulk phase is 10⁻⁴ m³ (100 cm³). This charge is tabulated in the last column of Table 1. It is immediately evident that for the first three species the charge is extremely small and probably undetectable in a normal experiment. Reactions (1.1), (1.2), and (1.3) are fast reactions and this estimate is reliable. In contrast, reaction (1.4) is a very slow reaction at this interface and it will not come to equilibrium in the normal time scale. At -0.8 V the current due to this reaction would be about 0.04 A m⁻². This is sufficiently small for its effect on the interfacial properties to be neglected. This example illustrates the thermodynamic (reactions (1.1), (1.2), (1.3)] and kinetic [reaction (1.4)] reasons for the absence of significant charge transfer. It confirms the view that the ideal polarized interface is a limiting case,

Table 1

Equilibrium Concentration of Species at the Interface Hg | KCI + H₂O at Two Different Potentials at 25°C and the Charge Required to Form
These Quantities in a Volume of 10⁻⁴ m³

Concentration	. E	H/V			
of minority species	-0.2V	Q/C

4 ROGER PARSONS

not one for which some special mechanism must be invoked. In spite of this, it is not incorrect to carry out the thermodynamic analysis as if there were a "barrier" at the interface which permits no charge to cross.

It is important to note that the concept of the ideal polarized interface includes the case where a local transfer of charge can take place. For example, on a platinum electrode at potentials up to about 300 mV positive of the equilibrium hydrogen potential, hydrogen ions from the solution adsorb, reacting with electrons from the metal to form essentially neutral hydrogen atoms. This reaction which may be represented as

$$H_{ads.} \rightleftharpoons H^+ + e$$
 (1.5)

is fast on platinum and so may be assumed to be in equilibrium except on very short time scales. Although (1.5) is a charge transfer reaction, it does not result in the net transfer of charge from one bulk phase to the other, as do reactions (1.4)–(1.4). From the point of view of the externally observable parameters which are used in a thermodynamic analysis, there is no distinction between the adsorption of H⁺ in the ionic form or in the atomic form, because the difference lies in the location of the charge within the interphase. This limiting case of charge transfer can in fact be identified by other methods and it was clearly recognized by Frumkin and his colleagues in their study of the platinum electrode in the 1930s. (11) However, the concept of a partial charge transfer and the way in which it enters the thermodynamic relations was enunciated by Lorenz and his coworkers from 1961. (12)

In this chapter the derivation of the thermodynamic relations will be made using the minimum of assumptions about the physical nature of the system. Specific assumptions may then be introduced in order to apply this more general treatment to specific physical situations, where other evidence indicates the nature of the interphase. Thus the general treatment of Sections 2 and 3 is followed by a series of more specific examples in Section 4 which illustrate the application of the thermodynamic method.

2. Thermodynamics of a Single Bulk Phase Containing Charged Particles

At first sight the simplest expression for the energy U of the bulk region of a single phase which may undergo thermal, mechanical, and matter exchange with its surroundings is

$$dU = T dS - p dV + \sum_{i} \bar{\mu}_{i} dm_{i}$$
 (2.1)

where T is the temperature, S the entropy, p the pressure, V the volume, m_i the amount of species i in the phase, μ_i is the electrochemical potential of species i if it carries a charge and the chemical potential if it carries no charge. The summation in Eq. (2.1) includes all independent components in the phase; that is, all

species whose concentration may be varied independently. It is usual to include ionic species or electrons separately in this summation and then to impose additionally the electroneutrality condition

$$\sum_{i} z_i m_i = 0 \tag{2.2}$$

since, as discussed above, only electrically neutral systems occur under normal conditions. The imposition of (2.2) allows any range of composition of positively and negatively charged particles provided that there is not an excess of charge of one sign.

However, the incorporation of Eq. (2.2) into Eq. (2.1) in a general way is cumbersome starting from the concept of ions as independent components, particularly when partial dissociation of some species exists in the sytem. Much of this difficulty can be avoided by adopting a more operational approach in terms of the amounts of species actually added to the phase when it is prepared. These are always uncharged species, metals in an alloy or "salts" in an electrolyte (the term "salt" here includes any neutral combination of ions such as an acid or a base as well as a conventional salt). Consequently, (2.1) may be replaced by

$$dU = T dS - p dV + \sum_{j} \sum_{k} \mu_{j,k} dm_{j,k}$$
 (2.3)

where $\mu_{j,k}$ is the chemical potential of an uncharged species present in an amount $m_{j,k}$. The sum is then over all components of the phase as defined in conventional thermodynamics, which is one less than the sum in Eq. (2.1). It is evident that this reduction in the number of components is a result of the fact that (2.3) includes the electroneutrality condition; in other words, (2.3) is a solution for (2.1) and (2.2). The species indicated by the subscript j, k may be a species which does not dissociate into ions or one which dissociates into two or more kinds of ions. Strictly speaking, therefore, a varying number of subscripts would be required to indicate these possibilities. The use of two subscripts covers the commonest case of two kinds of ions. Nondissociating species will be indicated by putting k = 0. It will be assumed that there are J types of cations, K types of neutral species and $J_0 - J$ types of nondissociating species. Thus the summation covers the range $1 < j < J_0$, 0 < k < K although not every combination of cation and anion is necessarily present; some of the $m_{j,k}$ may be zero.

If the species denoted by the subscript j, k dissociates into species carrying z_j , z_k unit charges, this species may be regarded as being composed of $\nu_{j,k}$ positively charged particles and $\nu_{k,j}$ negatively charged particles. In metallic phases $\nu_{j,k}=1$ and $\nu_{k,j}=z_j$, the number of electrons assumed to be produced by each metal atom (this number is arbitrary and may be taken as 1 or the conventional valency of the metal without affecting the thermodynamic argument). However, in electrolytes the relation between the charge number and the number of ions in the salt is not quite so simple, although it must always satisfy the

$$z_j \nu_{k,j} = -z_k \nu_{j,k} \tag{2.4}$$

A given ion may be present in more than one salt so that the relation between the m_i in Eq. (2.1) and the $m_{i,k}$ in Eq. (2.3) has the form

$$m_i = \sum_{k=1}^{k=K} \nu_{j,k} m_{j,k} \tag{2.5}$$

for the cations, or

$$m_i = \sum_{j=1}^{j=J} \nu_{k,j} m_{j,k} \tag{2.6}$$

and

$$m_i = m_{j,0} \tag{2.7}$$

for the nondissociating species. There are consequently $J_0 + K$ chemical species present in the phase, which as a result of the electroneutrality condition correspond to $J_0 + K - 1$ components.

It is convenient to define thermodynamic functions other than the energy. For a bulk phase, these are the enthalpy, H, the Helmholtz energy, A, and the Gibbs energy, G. These are defined by

$$H = U + pV \tag{2.8}$$

$$A = U - TS \tag{2.9}$$

$$G = H - TS \tag{2.10}$$

and it then follows from Eq. (2.3) that

$$dH = T dS + V dp + \sum_{j=1}^{j=J_0} \sum_{k=0}^{k=K} \mu_{j,k} dm_{j,k}$$
 (2.11)

$$dA = -S dT - p dV + \sum_{j=1}^{j=J_0} \sum_{k=0}^{k=K} \mu_{j,k} dm_{j,k}$$
 (2.12)

$$dG = -S dT + V dp + \sum_{j=1}^{s=J_0} \sum_{k=0}^{k=K} \mu_{j,k} dm_{j,k}$$
 (2.13)

It is frequently convenient to express the equilibrium condition for a bulk phase in terms of the variation of the intensive variables. Since Eq. (2.3) is a complete differential, the standard technique of integrating with respect to the extensive variables to yield

$$U = TS - pV + \sum_{j=1}^{j=1} \sum_{k=0}^{k=K} \mu_{j,k} m_{j,k}$$
 (2.14)

then differentiating

$$dU = T dS + S dT - p dV - V dp + \sum_{j=1}^{j=J_0} \sum_{k=0}^{k=K} (\mu_{j,k} dm_{j,k} + m_{j,k} d\mu_{j,k})$$
(2.15)

and finally, comparing (2.15) with (2.3) yields

$$S dT - V dp + \sum_{j=1}^{j=J_0} \sum_{k=0}^{k=K} m_{j,k} d\mu_{j,k} = 0$$
 (2.16)

This is the Gibbs-Duhem equation for this bulk phase.

3. Thermodynamics of an Interphase Containing Charged Particles

3.1. The Basic Equation

An interphase may be treated in a similar way to a bulk phase except that its dimension in one direction is very small, being perhaps a few molecular diameters, and the properties vary marked with position in this direction. Provided that the radius of curvature is large, the interphase may be regarded as plane and its energy then differs from that of a bulk phase by a term expressing the contribution of changes of energy due to a change of the area of contact, A_s , of the two phases. For a liquid/liquid interface, this energy contribution is γdA_s , where γ is the interfacial tension ("edge" effects are eliminated by considering a section of an interface in a larger system). Thus the energy is written as

$$dU^{\sigma} = T dS^{\sigma} - p dV^{\sigma} + \gamma dA_{s} + \sum_{j=1}^{j=J_{0}} \sum_{k=0}^{k=K} \mu_{j,k} dm_{j,k}^{\sigma}$$
 (3.1)

where the superscript σ indicates interfacial properties; since the intensive variables, T, p, and the $\mu_{j,k}$ are uniform through a system at equilibrium, no subscript is necessary for them.

The amounts of matter in the interphase, $m_{j,k}{}^{\sigma}$, differ from those in a bulk phase in that they are usually far from uniformly distributed in the direction perpendicular to the interface. In an equilibrium system the density of each substance is uniform in the directions parallel to the interface. The nonuniformity perpendicular to the interface does not prevent a discussion of this problem in terms of equations like (3.1), but it may require special discussion when some of the species present in one of the adjoining phases are not present in the other. The way in which this may occur for charged species has been discussed in Section 1 for the ideal polarized electrode. This situation may affect the number of independent variables in the system of two phases with the intervening interphase. It is therefore necessary to discuss the variance of such a system.

In a system of two phases α and β which contain, respectively, a and b components, it follows from (2.16) that there are a+b+4 independent intensive variables when the phases are separate. However, the existence of two equations like (2.16) means that the variance of the two separate phases is a+b+2. When the two phases are brought into contact and allowed to equilibrate this system as a whole is subject to a number of equilibrium conditions. If no component is common to both phases the additional conditions are

thermal equilibrium, hydrostatic equilibrium, and electrostatic equilibrium. The first and second conditions are expressed by the equality of temperature and pressure of the two phases and the (plane) interphase. The third condition means that there is a single electroneutrality condition for the system as a whole in place of the two electroneutrality conditions for the two phases separately. Thus in fact only one degree of freedom is eliminated and a+b+3 intensive variables remain. With the two Gibbs-Duhem equations for the separate phases this means that the variance is a+b+1.

Charge transfer between the two phases may occur in two ways, either by oxidation-reduction reactions, like $Fe^{2+} \rightleftharpoons Fe^{3+} + e$, between components which are present in only one phase, or by the transfer of a charged component from one phase to the other, like Fe^{2+} (m) \rightleftharpoons Fe^{2+} (s). If there are q types of charge transfer reaction of the first kind, then there are q equilibrium conditions and the variance is reduced to a + b + 1 - q. The second kind of charge transfer requires the presence of components common to both phases. If there are c such components then there are a' + c = a components in phase α and b' + c = b components in phase β . In the two phases separately there are then a' + b' + 2c + 4 intensive variables which on contact are reduced by 3 according to the thermal, hydrostatic, electrostatic, and Gibbs-Duhem conditionsdescribed above, but also by c conditions because of the identity of the c component in the two phases. The variance thus becomes a' + b' + c + 1, and in general for both kinds of charge transfer equilibrium and for the absence of charge transfer equilibrium the variance is C + 1 - q, where C is the total number of components in the two-phase system as a whole, the components being defined as neutral species in the way described in the previous section. If ionic components (described by m_i) are chosen the total number will be C' =C+2 and the variance is then C'-1-q. The summation in Eq. (3.1) will then consist of C-1-q (or C'-3-q) independent terms whereas it is written with C terms.

In the simplest example of a nonpolarizable interface there is one method of charge transfer and q=0 or 1, the dependent terms are then eliminated by using the Gibbs-Duhem equation for the two bulk phases. If q>1 there are relations between chemical potentials of species within each phase due to the oxidation-reduction equilibrium. The presence of such multiple equilibria does not bring any new features to the interfacial problem and it will not be discussed further here.

When charge transfer across the interphase occurs by only one species of reaction, it is convenient to separate the sum in Eq. (3.1) into two parts corresponding to the two phases adjoining the interphase. Many such systems are composed of an electronic conductor α and an ionic conductor β ; for such a system (3.1) may be written

$$dU^{\sigma} = T dS^{\sigma} - p dV^{\sigma} + \gamma dA_{s} + \sum_{j=1}^{j=J^{\alpha}} \mu_{j,e}{}^{\alpha} dm_{j,e} + \sum_{j=1}^{j=J_{0}^{\beta}} \sum_{k=0}^{k=K} \mu_{j,k}{}^{\beta} dm_{j,k}$$
(3.2)

since electrons are the only negatively charged species which need to be considered in phase α and no uncharged component j, k is common to both phases.

This equation may be used in this form; if this is done the potential difference E across the interface (measured with respect to an electrode reversible with respect to an ionic species in phase β) is a dependent variable, controlled by the charge transfer equilibrium across the interface. On the other hand, it is also useful to introduce this charge transfer equilibrium explicitly and to replace one of the chemical potentials with the electrical potential. In order to do this, it is necessary also to specify the ion in phase β to which the reference electrode is reversible. It will be assumed here that this is the ion N, which for convenience is taken to be an anion, while the equilibrium reaction in the interphase under study involves the cation M. The assumption that M and N have charges of different sign is not necessary; they may both be cations or both anions. However, if M and N are identical, it follows immediately that E is zero or constant and no useful information can be obtained by using this quantity.

If the interfacial reaction consists of the transfer of the ion M^{z+} between the phases, the equilibrium condition is

$$\tilde{\mu}_{\mathbf{M}^{z+}}{}^{\alpha} = \tilde{\mu}_{\mathbf{M}^{z+}}{}^{\beta} \tag{3.3}$$

which may also be written

$$\mu_{\mathbf{M}}^{\alpha} - z_{\mathbf{M}} \tilde{\mu}_{\mathbf{e}}^{\alpha} = \mu_{\mathbf{M}, \mathbf{N}}^{\beta} - (z_{\mathbf{M}}/z_{\mathbf{N}}) \tilde{\mu}_{\mathbf{N}}^{\beta}$$
 (3.4)

whence

$$z_{\mathbf{M}}(\tilde{\mu}_{\mathbf{N}}^{\beta}/z_{\mathbf{N}} - \tilde{\mu}_{\mathbf{e}}^{\alpha}) = \mu_{\mathbf{M},\mathbf{N}}^{\beta} - \mu_{\mathbf{M}}^{\alpha}$$
(3.5)

The quantity in brackets on the left-hand side of (3.5) will be defined as F_{ϵ} , where F is Faraday's constant. ϵ is a quantity directly related to the potential difference E between the terminals of the cell by the relation

$$\varepsilon = E + K \tag{3.6}$$

where K is a sum of chemical potentials of the components of the reference electrode and is independent of the composition of the phases α and β . Thus

$$z_{\mathbf{M}}F_{\varepsilon} = \mu_{\mathbf{M},\mathbf{N}}{}^{\beta} - \mu_{\mathbf{M}}{}^{\alpha} \tag{3.7}$$

The terms in the species M, N and M may then be extracted from (3.2),

$$\mu_{\mathbf{M}}{}^{\alpha} dm_{\mathbf{M}}{}^{\sigma} + u_{\mathbf{M},\mathbf{N}}{}^{\beta} dm_{\mathbf{M},\mathbf{N}}{}^{\sigma} \tag{3.8}$$

and in view of (3.7) may be rewritten in the form

$$-z_{\mathbf{M}}F\varepsilon dm_{\mathbf{M}}{}^{\sigma} + \mu_{\mathbf{M},\mathbf{N}}{}^{\beta} d(m_{\mathbf{M}}{}^{\sigma} + m_{\mathbf{M},\mathbf{N}}{}^{\sigma})$$
 (3.9)

The second term may be regarded as expressing the change in energy consequent on a change of the total amount of M^{z+} in the interphase, which can be denoted by $m_{\Sigma M}^{\sigma}$,

$$-z_{\rm M}F_{\rm E}\,dm_{\rm M}{}^{\sigma}\,+\,\mu_{\rm M,N}{}^{\beta}\,dm_{\rm \Sigma M}{}^{\sigma} \tag{3.10}$$

10 ROGER PARSONS

Note that in writing (3.4) it has been implicitly assumed that M, N is the only species containing M in phase β . (This assumption can be dropped at the expense of some further algebra.) The total amount of M in the interphase is a well-defined quantity independent of the state of the charge transfer reaction, or the distribution of charge in the interphase. However, $m_{\rm M}^{\alpha}$ is not so well defined because the amount of M (as metal atoms) does depend on the state of the charge transfer reaction. If it is assumed that the charge distribution in the interphase can be expressed in terms of an excess or deficiency of electrons on the side of the interphase adjoining phase α and a deficiency or excess of N ions on the side adjoining phase β , this may be related to $m_{\rm N}^{\alpha}$. Since all other components are considered to be present always in electrically neutral groups j, k, then $z_{\rm M} m_{\rm M}^{\alpha}$ may be taken to represent the excess of electrons on the phase α side of the interphase. This contributes a charge Q^{α} given by

$$Q^{\alpha} = -z_{\rm M} F m_{\rm M}{}^{\sigma} \tag{3.11}$$

This is necessarily equal and opposite to the charge on the phase β side of the interphase represented by the N ions:

$$Q^{\beta} = -Q^{\alpha} = z_{\rm N} F m_{\rm N}^{\sigma} \tag{3.12}$$

It must be noted first that this definition of charge has a formal character and second that it depends on the nature of the ion N to which the reference electrode is reversible, because this affects the division of the total amount of M^{z+} in the interphase into a part on the α side of the interphase and a part on the β side.

The full equation (3.2) may now be written in the form

$$dU^{\sigma} = T dS^{\sigma} - p dV^{\sigma} + \gamma dA_{s} \sum_{j=1}^{j=J^{\alpha}-1} \mu_{j,e}{}^{\alpha} dm_{j,e}{}^{\sigma} + \sum_{j=J^{\alpha}+1}^{j=J_{0}-1} \sum_{k=0}^{k=K-1} \mu_{j,k}{}^{\beta} dm_{j,k}{}^{\alpha} + \varepsilon dQ^{\alpha} + \mu_{M,N} dm_{SM}{}^{\sigma}$$
(3.13)

A similar modification can be made if the interfacial reaction is an oxidation-reduction reaction, represented by

$$M^{z+} \rightleftharpoons M^{(z+1)+} + e$$
 (3.14)

The equilibrium condition is

$$\tilde{\mu}_{M^{z+}}^{\beta} = \tilde{\mu}_{M^{(z+1)}}^{\beta} + \tilde{\mu}_{e}^{\alpha}$$
 (3.15)

which may be written

$$\mu_{M^{2+},N}^{\beta} + \tilde{\mu}_{e}^{\alpha} = \mu_{M^{(2+1)+},N}^{\beta} - \tilde{\mu}_{N}^{\beta}/z_{N}$$
 (3.16)

where N is again the ion (assumed to be an anion) in equilibrium with the reference electrode. Thus

$$F_{\varepsilon} = (-\tilde{\mu}_{N}^{\beta}/z_{N} - \tilde{\mu}_{e}^{\alpha}) = \mu_{M^{z+},N}^{\beta} - \mu_{M^{(z+1)+},N}^{\beta}$$
 (3.17)

The terms extracted from (3.2) are now

$$\tilde{\mu}_{M^{z+1}N}^{\beta} dm_{M^{z+1}N}^{\sigma} + \tilde{\mu}_{M^{(z+1)+1}N}^{\beta} dm_{M^{(z+1)+1}N}^{\sigma}$$
(3.18)

which with (3.17) may be written

$$-F\varepsilon dm_{\mathbf{M}^{(z+1)+},\mathbf{N}}^{\sigma} + \mu_{\mathbf{M}^{z+},\mathbf{N}}^{\theta} dm_{\Sigma\mathbf{M}}^{\sigma}$$
 (3.19)

where it is assumed that the ion M exists in the interphase only in the two forms taking part in the oxidation-reduction reaction (3.14). Thus again in (3.19) the second term represents the effect on the energy of variation in the total amount of M in the interphase. The first term may be regarded as expressing the effect of excess of unit positive charges on the phase β side of the interphase or

$$Q^{\beta} = Fm_{\mathbf{M}^{(z+1)+}, \mathbf{N}}^{\sigma} \tag{3.20}$$

so that when (3.19) is put back into Eq. (3.2) a form equivalent to (3.13) is obtained:

$$dU^{\sigma} = T dS^{\sigma} - p dV^{\sigma} + \gamma dA_{s} + \sum_{j=1}^{j=J^{\alpha}} \mu_{j,e}{}^{\alpha} dm_{j,e}{}^{\sigma} + \sum_{j=J^{\alpha}+1}^{j=J_{0}-2} \sum_{k=0}^{k=K-1} \mu_{j,k}{}^{\beta} dm_{j,k}{}^{\sigma} + \varepsilon dQ^{\alpha} + \mu_{M^{(\sigma+1)}+N} dm_{\Sigma M}{}^{\sigma}$$
(3.21)

the difference being that, here, two terms are lost from the sum for phase β and none from the sum for phase α instead of one from each.

The ideal polarized interface is a special case of the two types of non-polarizable discussed above. If it is assumed that in (3.13), $m_{\rm M}{}^{\alpha} \to 0$, the possibility of charge transfer vanishes. This causes modifications in the last two terms of (3.13). At first sight it would appear from (3.11) that Q^{α} also vanishes; however, it must be noted that this quantity actually represents the excess of electrons on the phase α side of the interphase. This in fact does not vanish as $m_{\rm M}{}^{\alpha} \to 0$, but becomes more precisely interpretable as a physical charge because there is no longer any ambiguity about the location of the M^{z+} ions, since they may all be attributed to the phase β side of the interphase. At the same time the last term of (3.13) expresses simply the effect of a change of the amount of MN on the phase side of the interphase.

Similar changes occur in (3.21) if the corresponding assumption is made, namely, that the concentration $m_{M^{(g+1)+N}}^{\alpha} \rightarrow 0$. Again the possibility of charge transfer vanishes and again the interpretation of the last two terms is modified. Q^{β} remains finite and becomes clearly related to a physical charge on the β phase side of the interphase because it represents the excess of unit positive charges. At the same time $m_{\Sigma M}^{\alpha}$ reduces to $m_{M,N}^{\alpha}$. Consequently, both (3.13) and (3.21) lead to the basic result

$$dU^{\sigma} = T dS^{\sigma} - p dV^{\sigma} + \gamma dA_{s} + \varepsilon dQ^{\alpha} + \sum_{j=1}^{j=J_{0}-1} \sum_{k=0}^{k=K-1} \mu_{j,k} dm_{j,k}^{\sigma}$$
(3.22)

in which the concentration terms for both phases are regrouped together and the sum covers all but one of the neutral components of the two bulk phases. If one of the terms of this sum is given the interpretation of the last term of (3.13) or that of the last term of (3.21), then it is possible to use the form (3.22)
