## Preface

The 9th Australasian Conference on Information Security and Privacy (ACISP 2004) was held in Sydney, 13–15 July, 2004. The conference was sponsored by the Centre for Advanced Computing – Algorithms and Cryptography (ACAC), Information and Networked Security Systems Research (INSS), Macquarie University and the Australian Computer Society.

The aims of the conference are to bring together researchers and practitioners working in areas of information security and privacy from universities, industry and government sectors. The conference program covered a range of aspects including cryptography, cryptanalysis, systems and network security.

The program committee accepted 41 papers from 195 submissions. The reviewing process took six weeks and each paper was carefully evaluated by at least three members of the program committee. We appreciate the hard work of the members of the program committee and external referees who gave many hours of their valuable time.

Of the accepted papers, there were nine from Korea, six from Australia, five each from Japan and the USA, three each from China and Singapore, two each from Canada and Switzerland, and one each from Belgium, France, Germany, Taiwan, The Netherlands and the UK. All the authors, whether or not their papers were accepted, made valued contributions to the conference.

In addition to the contributed papers, Dr Arjen Lenstra gave an invited talk, entitled *Likely and Unlikely Progress in Factoring*.

This year the program committee introduced the Best Student Paper Award. The winner of the prize for the Best Student Paper was Yan-Cheng Chang from Harvard University for his paper *Single Database Private Information Retrieval with Logarithmic Communication*.

We would like to thank all the people involved in organizing this conference. In particular we would like to thank members of the organizing committee for their time and efforts, Andrina Brennan, Vijayakrishnan Pasupathinathan, Har-tono Kurnio, Cecily Lenton, and members from ACAC and INSS.

**Abstract.** Multi-service oriented broadcast encryption is a mechanism that allows a center to securely distribute multiple services to its authorized users. In this paper, we suggest a framework called  $\mathcal{M}$  framework from the subset cover method [12] using RSA exponentiation technique. In this framework, each user's secret storage is independent of the number of services. Service subscriptions and service providing can be efficiently processed. The service unsubscriptions are dealt scalably. A small number of service unsubscriptions can be handled without key updating while the number of such users reaches a threshold, a rekeying algorithm is proposed to update the user's service memberships *explicitly*. We formalize and prove the framework is dynamically secure under the random oracle model. We realize our framework with a scheme based on complete subtree method.

## 1 Introduction

Broadcast encryption is a mechanism that allows one party to securely distribute his data to privileged users. This mechanism has important applications in Pay-TV, stock quotes and online database, etc. After the work by Fiat and Naor in 1993 [9], it has been extensively studied in the literature, for example, schemes for stateless receivers [1,12], public key based schemes [2,6,14] and rekeying schemes [16,15,4,10].

In this paper, we consider the multi-service oriented broadcast encryption (MOBE), which is explained as follows. Suppose that a broadcast center (BC) wants to distribute multiple services to a set of users such that each user is allowed to access a specific service if and only if he has subscribed to it. Here the security concerns are traitor tracing, service unsubscriptions, etc. A possible solution is to associate each service with a distinct system (in a single service setting). The main problem here is that a user's secret storage is proportional to the number of his subscribed services.

### 1.1 Related Work

MOBE problem is related to flexible access control by Chick and Tavares [5], where each user is assigned a master key using RSA exponentiation technique

that allows him to access his subscribed services. However, users get an identical key set if they subscribe the same services. Thus, it is impossible to distinguish such users. Consequently, traitor tracing and service unsubscriptions are not achievable.

Narayanan, et al. [13] considered a multi-service notion called practical Pay-TV scheme. They proposed three schemes. The third one is the most interesting scheme which is secure and has traceability. However, their scheme is only suitable for application with a small number of services since the user key size is linear in the number of subscribed services. Furthermore, their service unsubscription utilizes a unicast channel. It follows that it is not suitable for applications with a large number of users or applications with frequent membership updating. The second scheme claimed the collusion can not compute the secret associated with service  $i$ . But we show that this is incorrect in the full paper [11].

## 1.2 Contribution

In this paper, we propose a framework called  $\mathcal{M}$  framework for MOBE problem. We first achieve the multi-service functionality from the subset cover method [12] (in the single service setting) using RSA exponentiation technique. But this is not sufficient since it might become less efficient( e.g., the message overhead grows large; it increases management burdens; revoked IDs can not be reused) when unsubscription is frequent, due to lack of a rekeying mechanism. We thus propose a multi-service rekeying algorithm by extending a rekeying framework [7,10]. In the obtained full framework, user key size in  $\mathcal{M}$  is independent of the number of services. Subscription and new service providing are handled without involving unintended users. Furthermore, service unsubscription is handled scalably, which makes the system flexible. To gain a better understanding of this framework, we realize it by an efficient scheme  $\mathcal{M}_{cs}$ , which is based on a complete subtree method [12]. Finally, in order to evaluate the security of our framework, we formalize a notion of *dynamic security*. It captures threats from an adaptive adversary that might issue queries such as subscription, rekeying, corruption and new service providing. We show that  $\mathcal{M}$  framework is secure under such a *severe* attack. Our proof is in the random oracle model.

This paper is organized as follows. In Section 2, we introduce our  $\mathcal{M}$  framework and show their features. In Sections 3, we present a realization of  $\mathcal{M}$  framework, from complete subtree method. In Section 4, we formalize and prove the dynamic security of  $\mathcal{M}$  framework.

## 2 A Framework for Multi-service Oriented Broadcast Encryption

In this section, we introduce our  $\mathcal{M}$  framework for MOBE problem and show some advantages of this framework.

## 2.1 Description of $\mathcal{M}$ Framework

Let  $U$  be the set of all possible users; BC be the broadcast center;  $w$  be the number of services BC provides. BC wants to provide services  $\{1, \dots, w\}$  with a controlled access right.

### Preprocessing Phase

1. BC chooses a RSA composite  $N = pq$  and  $w$  primes  $p_1, p_2, \dots, p_w$ , where  $p, q$  are two large primes. Then he makes  $N, p_1, \dots, p_w$  public and keeps  $p, q$  secret.
2. BC defines a collection of subsets of  $U$ :  $S_1, S_2, \dots, S_z$ , where  $z$  is polynomially bounded. For security reason, we require that  $\{u\}$  is contained in the collection for all  $u \in U$ . Then BC associates  $S_i$  with a secret number  $k_i, i = 1, \dots, z$ .
3. BC defines  $Q = \prod_{i=1}^w p_i$ . Let  $\{1, 2, \dots, w\}$  be the set of services currently available,  $B(u)$  be the set of services user  $u$  has subscribed,  $Z(u) = \prod_{i \in B(u)} p_i$ , and  $K(u) = \{k_i^{Q/Z(u)} \pmod{N} | u \in S_i, i = 1, \dots, z\}$ .

Note that without a special mention in this paper we always assume that the exponentiation is carried out over modular  $N$ .

**Join Phase.** When a new person asks for join, BC first finds a free ID  $u \in U$  and assigns  $K(u)$  and a random subscription key  $c_u$  to this person. Here  $c_u$  is only for subscription use and remains unchanged as long as he is in the system. We denote this person simply by  $u$  when the context is clear.

**Broadcast Phase.** Let  $U_i$  be the set of all the users that subscribe service  $i$ . When BC wants to broadcast message  $M$  of service  $i$  to all users in  $U_i \setminus R_i$ , for some  $R_i \subseteq U_i$ , he first finds a set cover  $S_{i_1}, S_{i_2}, \dots, S_{i_m}$  for  $U \setminus R_i$ , i.e.,  $S_{i_1} \cup S_{i_2} \cup \dots \cup S_{i_m} = U \setminus R_i$ . He then forms the ciphertext as

$$\mathcal{H}_i(R_i, M) := \langle i_1, \dots, i_m, E_{sk_{i_1, i}}(k), \dots, E_{sk_{i_m, i}}(k), F_k(M) \rangle, \quad (1)$$

where  $sk_{i_j, i} = f(k_{i_j}^{Q/p_i})$ ,  $E$  and  $F$  are two encryption algorithms (usually  $E$  has a higher security than  $F$ ),  $f : Z_N^* \rightarrow \{0, 1\}^L$  is a public hash function where  $L$  is the key size of  $E$ .

**Decryption Phase.** When receiving  $\mathcal{H}_i(R_i, M)$ , a user  $u$  in  $U_i \setminus R_i (\subseteq U \setminus R_i)$  first finds  $j$  such that  $u \in S_{i_j}$ . Since  $u$  has  $k_{i_j}^{Q/Z(u)}$ , he can compute  $sk_{i_j, i}$  and obtain message  $M$ .

**Subscribing More Services.** We now show that it is convenient for an existing user  $u$  to subscribe more services. Suppose  $u$  wants to add service  $j$  to  $B(u)$ . He first updates  $B(u)$  to  $B'(u) = B(u) \cup \{j\}$ ,  $Z(u)$  to  $Z'(u) = Z(u) \times p_j$ .

BC then provides a key set  $\{k_i^{Q/p_j} | u \in S_i, i = 1, \dots, z\}$  to  $u$  encrypted under the subscription key  $c_u$ . When  $u$  gets this key set, he can update  $K(u)$  to  $K'(u) := \{k_i^{Q/z'(u)} | u \in S_i, i = 1, \dots, z\}$  as follows. He finds integers  $a, b$  using the Euclidean algorithm such that  $p_j a + bZ(u) = 1$  and then computes

$$(k_i^{Q/Z(u)})^a (k_i^{Q/p_j})^b = k_i^{aQ/Z(u)+bQ/p_j} = k_i^{\frac{Q}{Z'(u)}(p_j a + Z(u)b)} = k_i^{Q/Z'(u)}.$$

It is clear that  $K'(u)$  is the current key set for user  $u$ . For simplicity, we still denote the updated parameters as  $K(u), B(u), Z(u)$ , respectively.

**Service Unsubscription.** Some users  $R'_i$  may quit service  $i$  at some moment. The main concern is to prevent them from access to it again after their leave. If the size of  $R'_i$  is small, this can be handled without updating other users' secret information. Specifically, in the broadcast phase, BC can use a set  $R_i$  containing  $R'_i$  as the excluding set. However, as mentioned in the introduction, when the size of  $R'_i$  grows large, this method is inefficient. In our method, we propose an extension of a rekeying algorithm [7] to *explicitly* update users' service memberships, see the rekeying phase.

**Providing New Services.** We show that it is convenient for BC to provide a new service  $(w+1)$ . To do this, BC first finds a prime number  $p_{w+1}$  and updates  $Q$  to  $Q' = Q \times p_{w+1}$ . Then he computes  $q_{w+1} = p_{w+1}^{-1} \pmod{\phi(N)}$ , where  $\phi(\cdot)$  is the Euler function. For each  $k_i$ , he computes  $k'_i := k_i^{q_{w+1}}$ . For an existing user  $u$ , his secret key information keeps invariant since  $k_i^{Q'/Z(u)} = k_i^{Q/Z(u)}$ . If  $u$  wants to subscribe service  $(w+1)$ , BC provides  $p_{w+1}$  and  $\{k_i^{Q'/p_{w+1}} | u \in S_i, i = 1, \dots, z\}$  to him, encrypted under  $c_u$ . Then  $u$  updates  $B(u), Z(u), K(u)$ .

As a summary, providing a service does not affect an existing user's activity or even he does not need to know about this new service. On the other hand, subscribing this new service is as easy as subscribing an existing service.

**Rekeying Phase.** When the size of the set  $R_i$  for quitting a certain service  $i$  grows large, the system will become inefficient. Thus it is desired to permanently update users' service memberships. Let  $\Delta : U \rightarrow \{1, \dots, w\}$  be a function such that  $\Delta(u)$  is the set of services that  $u$  will quit in this rekeying event. Note that revoking an illegal user is looked as quitting all the services. Now we extend a rekeying algorithm in [7] to the multi-service setting. We remark that the rekeying algorithm in [7] is an extension of that in [10]. Let  $R$  be the set of users that will quit at least one service. Then for a given pair  $(R, \Delta)$ , we can *simultaneously* update every user's key information (for all possible services). In order to present the algorithm in a clear way, we introduce some notations.

**Definition 1.** Define  $C(k_i)$  to be the minimal subset of  $\{k_1, \dots, k_z\}$  containing  $k_i$  such that generation process for elements in  $C(k_i)$  shares no random bits with generation process for elements in  $\{k_1, \dots, k_z\} \setminus C(k_i)$ .
