Experimental Approach to Electrochemistry

N. J. Selley M.A., B.Sc.

Senior Lecturer, Kingston Polytechnic (Gipsy Hill Centre).

Edward Arnold

To H. G. Andrew

Preface

This book treats a well-established subject in a new way. The content matter corresponds approximately to the basic electrochemistry component of an ordinary degree course in chemistry, but the style of treatment will be seen to be more expansive and less mathematical than the usual student text. (No more than O-level maths is presupposed.)

The first two chapters are devoted to a closer look at topics first met with at O-level, with the intention of revealing aspects which the now more mature reader will appreciate. It is hoped that this critical approach to elementary material will be of particular interest to (present or prospective) science teachers.

After what may serve as a revision of earlier work, the book proceeds (in Chapters 3 to 6) to examine the concepts and principles shown on the diagram overleaf. The aim is full understanding rather than rapid coverage, and the practical work and exercises are designed to assist in this. The practical work does not require elaborate or expensive apparatus, and it should be possible to carry out most of it in a very modestly equipped laboratory. The book may be used either with an organized course or for private study, and in the latter case the student will benefit from the fuller 'Answers', which include indications as to the method of working the exercises.

Chapters 7 and 8 continue with an account of some analytical and technical applications of electrochemistry. The intention here is to illustrate the principles and point to the variety of their practical applications, not to give full working instructions for the techniques.

An unusual feature of the book is that the last chapter is entirely devoted to suggestions for individual research or further study projects, over a range of levels of difficulty corresponding to the rest of the book (and in some cases a little beyond). I hope that this chapter will assist lecturers who wish to develop courses based in the laboratory rather than the lecture theatre, and I believe that electro-chemistry—a comparatively safe, clean and manageable subject—is a suitable area for experiments along these lines. In schools, too, there may be teachers who reject the view that the need to 'cover the syllabus' (of, say, two or three A-levels) precludes a more searching study of any one topic. They may find that this book enables their students to work individually for a couple of months, each at his

own pace, pursuing the study to the point where it becomes a real intellectual challenge.

An analysis of the relations between the concepts of basic electrochemistry

On this diagram the concepts have been placed at the level where full understanding becomes possible. Many of the concepts can be *used* in routine situations at a much lower level. This applies particularly to the two equations which lie across the boundary between central and upper sections.

The boundaries are arbitrary, and correspond roughly to years of a three-year course. The lower section contains ideas first met in 'O' level and mastered by lower VI; the central area contains ideas which are normally dealt with in some depth for 'A' level; while the upper areas show concepts which, though closely associated with or even fundamental to the others on the diagram, are generally regarded as college or university level.

Diagram — concepts and relations in basic electrochemistry:

- non-ideality / Interionic attraction theory
- Kohlrausch's Laws
- limiting molar ionic conductivity
- molar conductivity
- conductimetric titrations
- Equilibrium
- strong and weak electrolytes
- conductance
- Moles
- conduction

$$\Delta G^\ominus = -RT \ln K; \quad E^\ominus = \frac{RT}{zF} \ln K$$

- polarography
- over-potential
- Chemical Dynamics
- minimum decomposition potential
- $\Delta G = \text{max reversible work}$
- $\Delta G = \Delta G^\ominus - RT \ln Q_c$
- Reversibility
- Derivation — $\Delta G = -zFE$ — Use
- electrode potentials | - redox potentials
- potentiometry
- Faraday's Laws (stoichiometry)
- electrode reactions

$$\left(\frac{\partial E}{\partial T}\right)_c = \frac{\Delta S}{zF}$$

- Free Energy
- reversible cell potential
- p.d. of working cell
- electrolysis
- simple galvanic cells
- electric current
- Derivation — $E = E^\ominus + \frac{RT}{zF} \ln Q_c$ — Use
- potentiometric titration
- e.m.f. of cells
- Entropy
- Free Energy
- Enthalpy of Reaction
- Free Energy

Some Basic Facts

1.1 Conduction

Most simple systems which conduct electricity obey Ohm's Law, though electrolytes with direct current may need a 'minimum decomposition potential' (§4.2) of up to 2 volts before significant current passes. Ohm's Law states that the current I is proportional to the potential difference E across any conductor, so:

$$E = IR \quad \text{or} \quad I = EG$$

where the constants of proportionality are called the resistance R and the conductance G. If E is measured in volts and I in amperes, R will have the unit volts per ampere, named the ohm and given the symbol Ω. Since conductance is the reciprocal of resistance, G will have the unit Ω^{-1}, at one time called the mho. Electricians, but not often chemists, refer to the reciprocal ohm as the siemens.

The resistance of a particular body is usually proportional to the length l of the path of the current, and inversely proportional to the cross-sectional area a. Therefore in order to eliminate the geometry of the particular sample, and to obtain the *resistivity* of the substance, the resistance is multiplied by (area/length). The common unit of resistivity is Ω cm.

Similarly, *conductivity* κ (kappà) is obtained by the relationship

$$\kappa = \frac{l}{a} G \quad \text{or} \quad I = \kappa E \frac{a}{l}$$

Conductivities of various substances may be compared, roughly, by means of a circuit consisting of a 6 V supply, an ammeter, a pair of copper plates, and a variable resistor (rheostat) of about 20 Ω, adjusted to give full-scale deflection on the meter when the copper plates are in contact. The 'ohms' range of any multi-range meter will serve the same purpose. For solids, similarly sized samples are pressed between the plates; and for liquids, the plates are immersed to some standard depth. More careful methods of measurement will be discussed in Chapter 3.

In the case of metallic (electronic) conductors and semiconductors, no chemical change results from the passage of the electric current, but when a current passes through an electrolyte there is invariably chemical reaction at the electrodes (for alternating current see §3.3). The electrodes are the points of contact where the

Table 1.1 Results of Conductivity Tests

			Examples
(i)	Very good conductors	All metals (solid* or molten)	Fe, Pb, Na, Hg
(ii)	Good conductors	Some compounds (electrolytes) when molten, but not solid.	NaOH, PbBr$_2$
		Some aqueous solutions of salts, acids and bases (electrolytic solutions)	NaOH, H$_2$SO$_4$, CuCl$_2$
		Graphite	C(gr)
(iii)	Poor conductors	A few solid compounds (solid electrolytes)	AgCl
		Solutions of weak (slightly dissociated) electrolytes	CH$_3$COOH(aq), NH$_3$(aq)
(iv)	Very poor conductors†	A few pure liquids (slightly ionized)	pure H$_2$SO$_4$, H$_2$O
(v)	Non-conductors	Non-metal elements (solid or liquid)	S, Br$_2$, C (diamond)
		Molecular compounds (non-electrolytes)	CCl$_4$, C$_6$H$_6$, PCl$_5$
		Some aqueous solutions (non-electrolytes)	C$_{12}$H$_{22}$O$_{11}$, CO(NH$_2$)$_2$ sucrose urea

Gases conduct only at low pressures and with high potential differences.

---

* *Powdered* metals may appear to conduct badly because of poor contact between particles.

† These very weak electrolytes show a misleadingly high conductivity unless specially purified.

current enters or leaves the electrolyte, that is, where there is a change from electronic to electrolytic conduction.

An interesting difference between metallic and electrolytic conductors is the effect of temperature on conductance. The conductance of metals decreases with rise in temperature, though the effect is not very pronounced; but the conductance of electrolytes increases markedly with increasing temperature—it may increase by a factor of five from 10°C to 80°C. (Graphite is anomolous in that it is an electronic conductor which increases its conductance on heating: carbon filament lamps exploit this property.)

The explanation of this difference is that since the conduction in electrolytes is due to the movement of ions (electrically charged atoms or molecules), there is considerable friction or viscosity within the electrolyte; so an increase in temperature, and freer movement of the particles, reduces this friction. In metals, however,

conduction is due to the movement of electrons, which may be pictured as small and fast-moving compared to atoms; a rise in temperature causes an increase in the space between the atoms, which hinders the electron flow.

1.2 Ionic theory

X-ray crystallography shows that solids consist of regular crystal lattices, but while some solids have the same unit (the molecule) at all lattice points, others (the 'ionic' solids) have two (or more) different types of unit. In the ionic crystal, any one ion is surrounded by several (often 6) oppositely-charged ions, all equally distant. No ion is connected to any other particular ion: there are no ion-pairs such as Na–Cl or Ca–SO_4 in the solid (though they are predominant in the vapour).

Molecular solids melt and boil at relatively low temperatures, showing that although the bonds within molecules are strong, the forces between molecules are weak. In contrast, ionic solids melt at high temperatures, showing the strong forces between the particles—forces which are interpreted as attractions between oppositely-charged ions.

The modern theory of electrolyte solutions is due to Arrhenius, who announced it in 1883 although it was not generally accepted until 20 years later. The theory is that all solutions of 'strong' electrolytes consist entirely of ions, now known to be 'hydrated' by association with a number of solvent molecules.[1] Thus aqueous sodium chloride solution is $Na^+(aq) + Cl^-(aq)$, with no NaCl molecules; and aqueous H_2SO_4 is almost entirely $H^+(aq)$, $HSO_4^-(aq)$ and $SO_4^{2-}(aq)$.
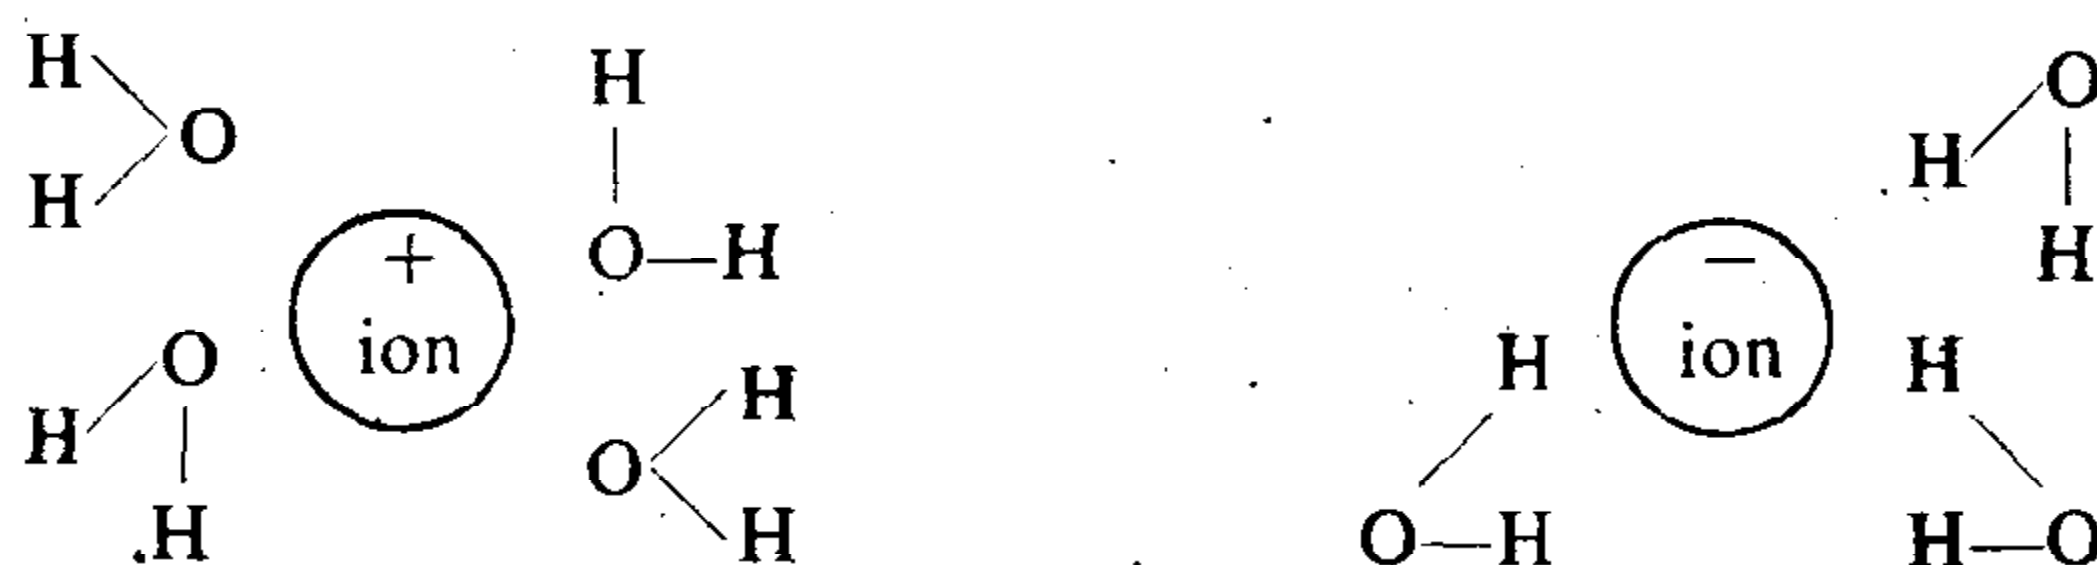

Chemists in 1890 found this hard to accept because they did not understand the important difference between ions and atoms. Since sodium and chlorine combine so vigorously to form sodium chloride, it was difficult to believe that merely dissolving the salt in water could separate the sodium and chlorine. They were happier with an earlier theory of dynamic equilibrium between dissolved molecules and a *small proportion* of ions, since this would not require so much 'energy of ionization'.

[1] The manner and extent of hydration of aqueous ions are not properly understood, and only recently have techniques such as the effect of high pressure on conductivity begun to provide answers. There is little doubt, though, that the hydration arises from electrostatic attraction between the ion and either the partly negative O or the positive H atoms of appropriately oriented H_2O molecules. The energy of hydration (and hence the number of molecules held) is a function of the charge density on the ion (which increases with smaller size and higher charge).

Fortunately van't Hoff had provided evidence of a non-electrochemical kind: his vapour pressure measurements on aqueous solutions only made sense if the electrolyte solutions contained a number of particles twice or three times as great as that of these supposed 'molecules' of the electrolytes. The depression of the vapour pressure of 1 dm^3 of water by 1 mole of $CaCl_2$ approached a value three times as great as that caused by 1 mole of the non-electrolyte urea; that is, the van't Hoff factor i was approximately 3.

However, conductivity and vapour pressure measurements on solutions of some acids and bases showed that they existed largely as molecules with only a small proportion of 'dissociation' into ions. These were the 'weak electrolytes',[2] for example ethanoic (acetic) acid, hydrocyanic (prussic) acid, or ammonia solution.

The ionic theory for strong electrolytes gained further support from the X-ray crystallography results mentioned at the start of this section. If salts are fully ionized in the solid state, it was argued, then no energy will be required to ionize them when they dissolve. This point is not so sound as it seemed at the time, and the objections are (i) the dissolution of a salt in water *is* accompanied by an energy change, which is sometimes so great an absorption of energy as to make the salt insoluble: (ii) some electrolyte solutions are formed by the dissolution of *molecular* solids or liquids (e.g. H_2SO_4, $AlCl_3$), yet these processes are often exothermic, despite the supposed 'energy of ionization'. The misunderstanding lay in supposing that the energy of ionization would be simply that for the splitting of the molecule into fragments, with the breaking of bonds; but in fact this energy is more or less regained when the anhydrous ions combine with water to give hydrated ions. This is shown in Fig. 1.1, which displays diagramatically the energy (enthalpy) changes which would accompany a *hypothetical* route from solute to solution via free gaseous anhydrous ions. It is not suggested that these free ions are actually formed as intermediates in the process of dissolution, but such an analysis helps to explain differences in the solubilities of different electrolytes.

The ionic theory readily explains the conductance of electricity through the bulk of the molten or dissolved electrolytes, since in these states the ions are free to move, and those with positive charge (the cations) will move towards the negative electrode, while the negative ions (anions) drift towards the positive electrode. But what happens when the ions reach the electrode is another matter; there must be a change from electrolytic to electronic conductance. Therefore there must be a discharge or creation of ions and an absorption or release of electrons. Fig. 1.2 shows the movement and discharge of ions during the electrolysis of ZnI_2 solution.

Practical work

A simple but convincing demonstration of the movement of ions (electrophoresis) is given by the electrolysis of copper(II) dichromate(VI) solution in a U-tube, with dilute sulphuric acid in the two limbs (Fig. 1.3). As the current passes, a blue colour

---

[2] Note that since 'weak' and 'strong' are used to indicate partial and complete dissociation, these words should not be used to mean 'dilute' and 'concentrated'.
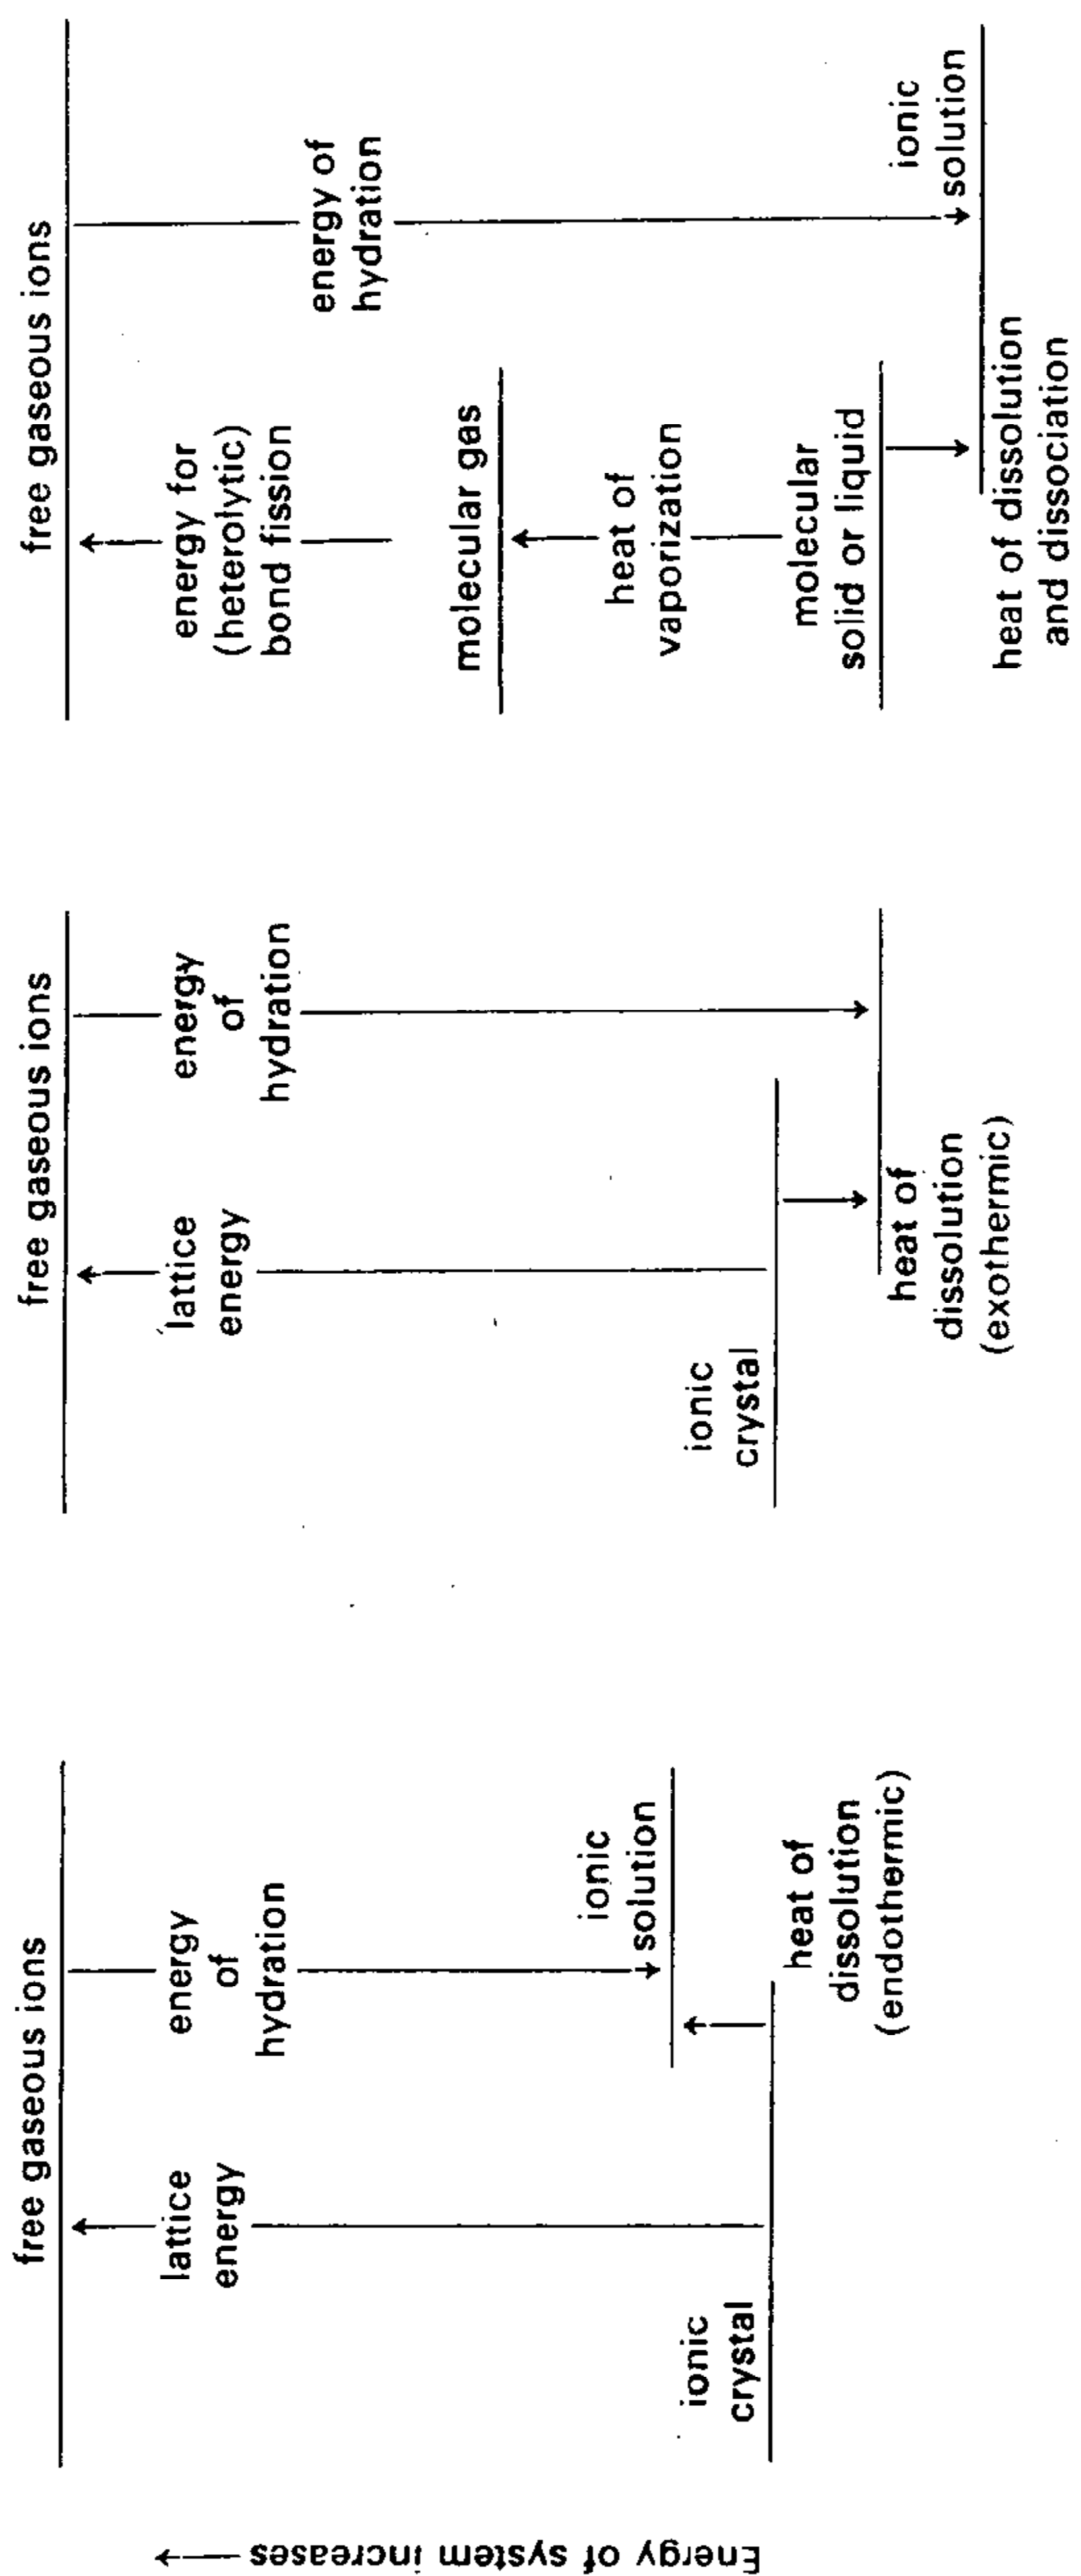

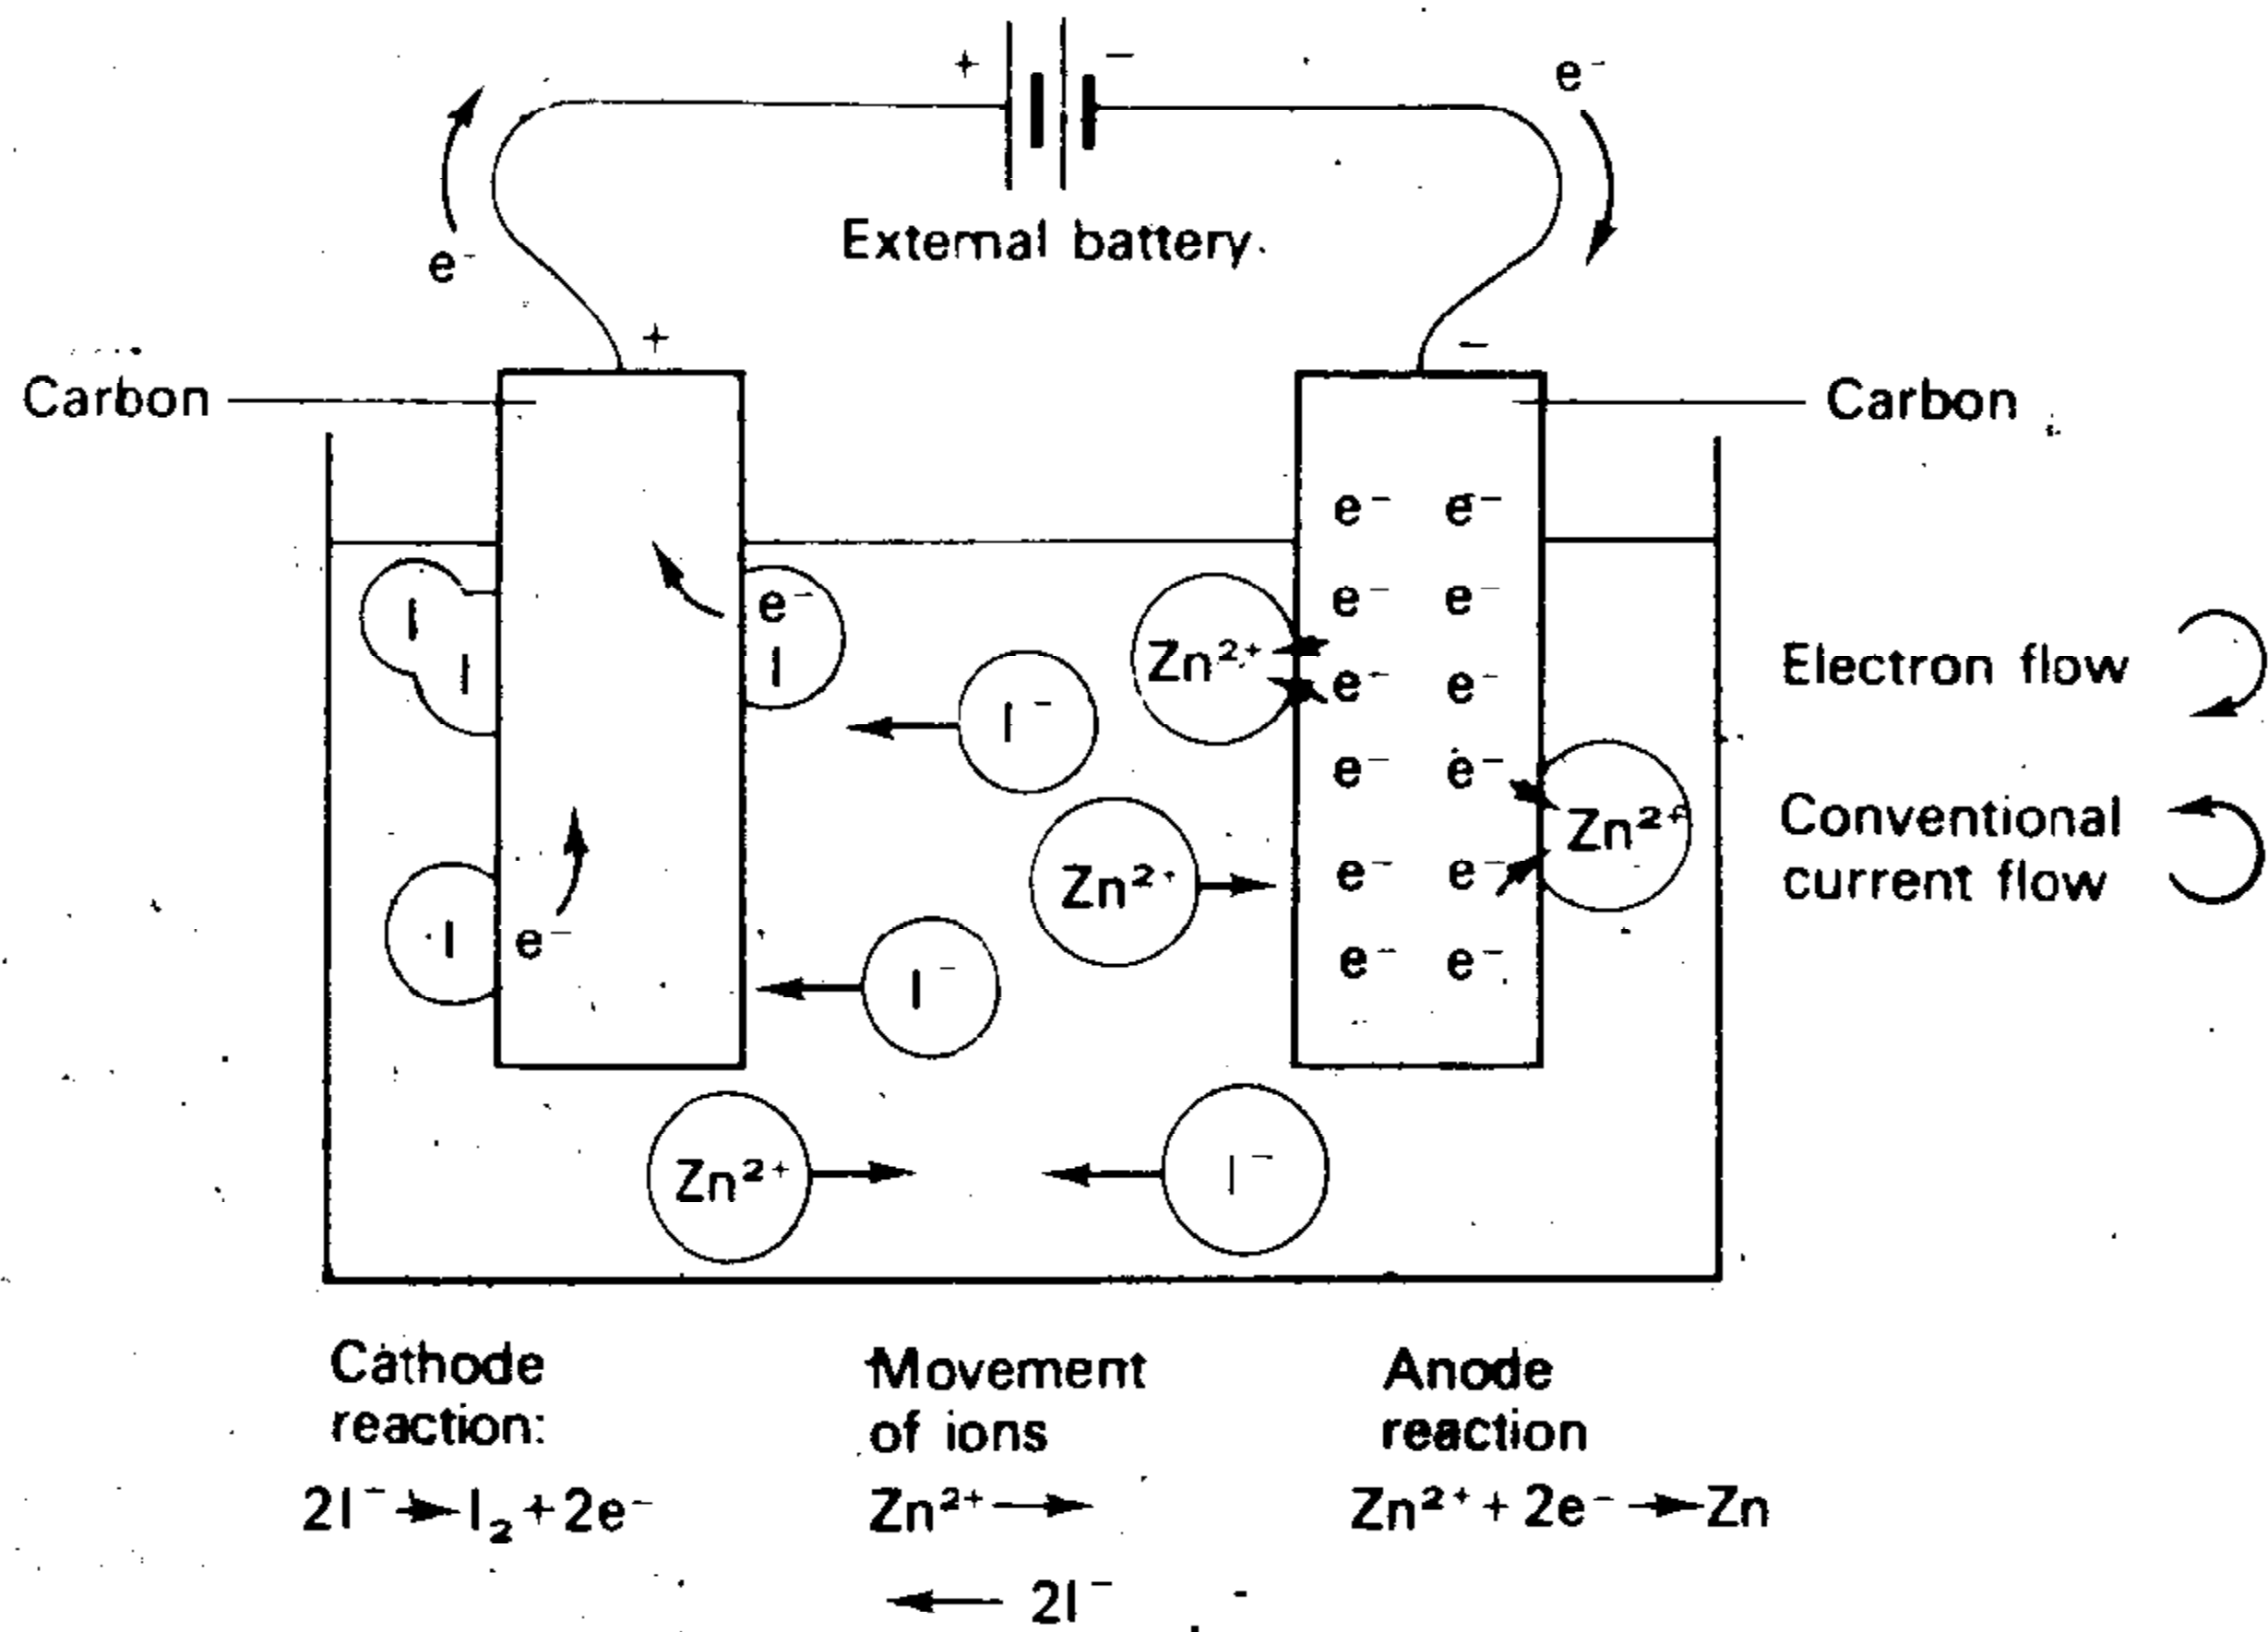

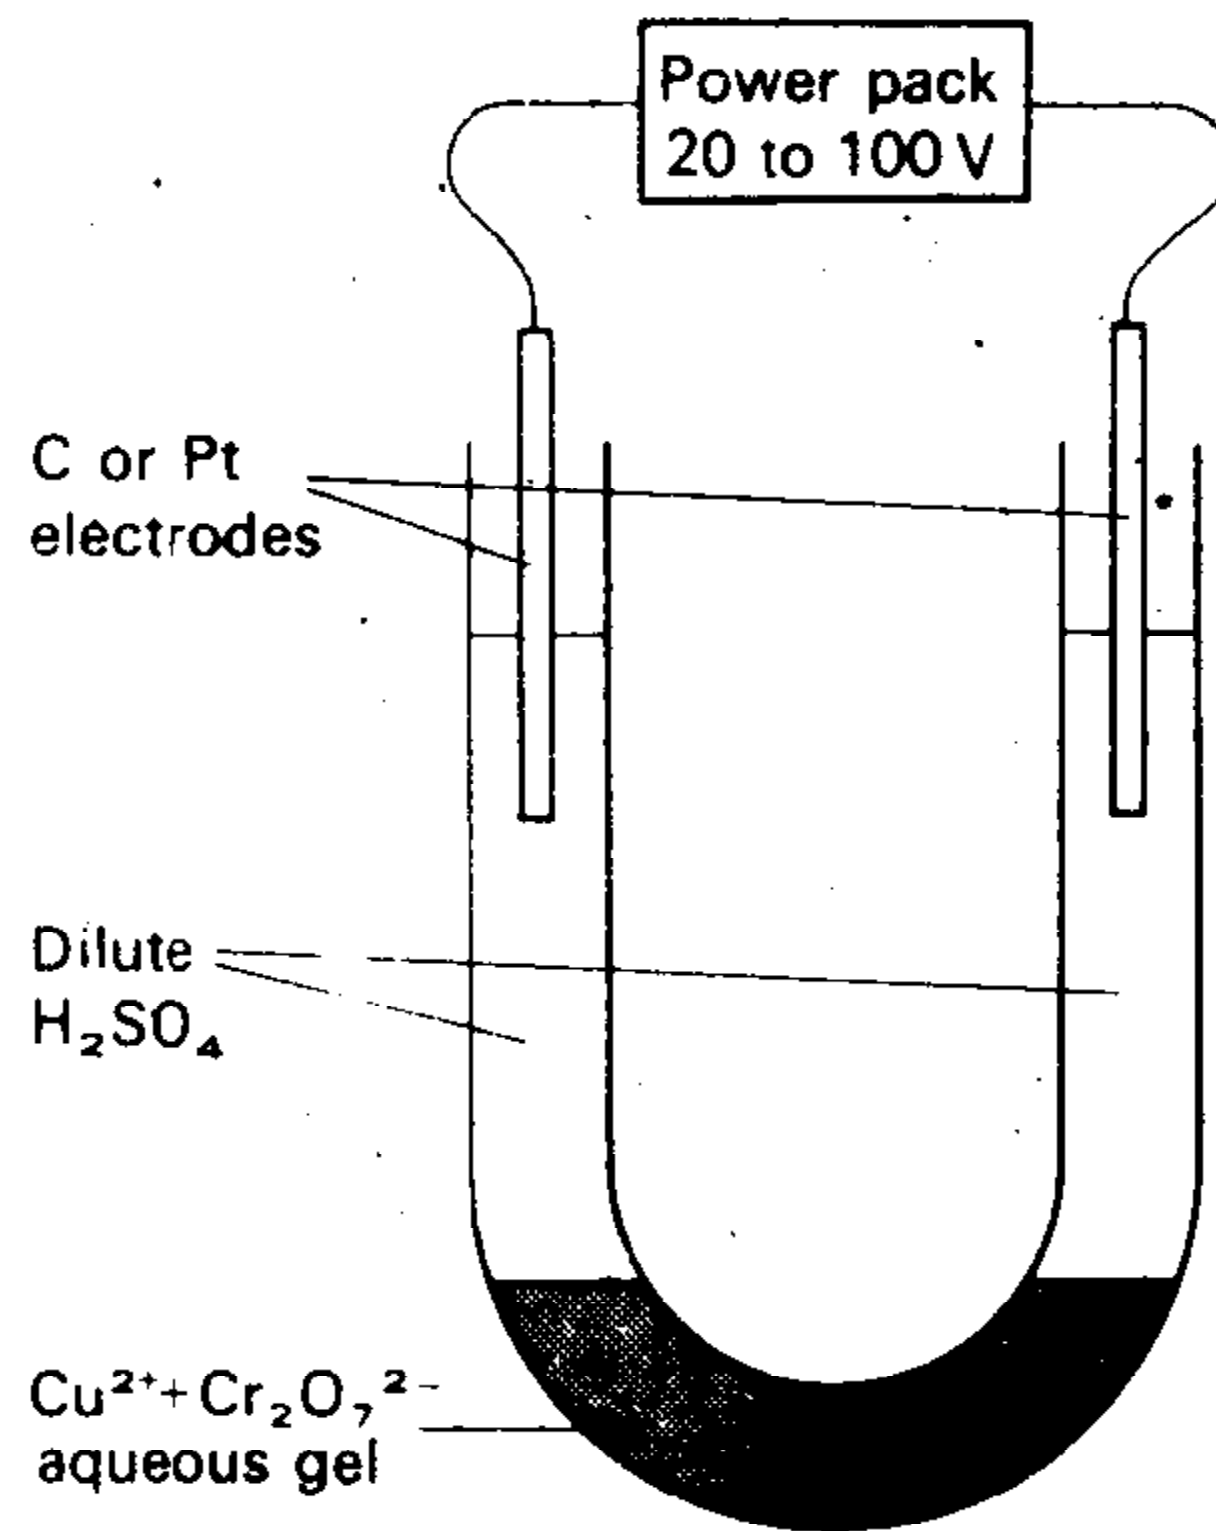

Fig. 1.1 Analysis of energy changes for hypothetical routes (thermochemical cycles) for the formation of electrolytic solutions

Fig. 1.2 Electrolysis. The processes comprising the electrolysis of aqueous zinc iodide solution

Fig. 1.3 Demonstration of the movement of ions during electrolysis

appears in the acid in which the negative electrode is placed, due to the migration of Cu^{2+}(aq) ions. Simultaneously, orange $Cr_2O_7^{2-}$(aq) ions migrate towards the positive electrode. Even with a potential difference of 20 V, about 15 minutes is required to give clearly visible colours in the limbs of the U-tube, which gives an impression of the slowness of the drift of ions. Practical details for setting up this demonstration, and also a version for individual work, are given in Appendix II (p. 194).

A similar but quicker demonstration is provided by the migration of MnO_4^- when electrodes with a potential difference (p.d.) of about 100 V d.c. are placed each side of a single crystal of potassium manganate(VII) on a filter paper moistened with dilute sulphuric acid. An elongated purple stain grows out from the crystal, on one side only.

The use of electrophoresis to separate ions for the purpose of qualitative analysis is the subject of a Project in Chapter 9.

1.3 Chemical changes in electrolysis

Unlike electronic conduction, electrolytic conduction is always accompanied by chemical changes at the electrodes. In some cases the electrodes are attacked, but in other cases they are inert, and then the chemical changes involve only the electrolyte. Despite the variety of possibilities, certain rules are obeyed in all electrolyses:

(1) At the negative electrode, electrons are forced to leave the metallic (or carbon) electrode and take part in an electron-absorbing reaction, most commonly the discharge of a metal ion or hydrogen ion. This results in the formation of a metal plating on the electrode, or the production of hydrogen gas.

(2) At the positive electrode, the externally imposed potential difference causes a deficiency of electrons, thereby encouraging any electron-releasing reaction such as the dissolution of the metal electrode in the form of positive ions, or the discharge of negative ions to produce oxygen, chlorine or another non-metal.

(3) The sum total of these 'half-reactions' at the two electrodes is a complete chemical reaction, but one which would not have occurred without the supply of electrical energy. It is often the exact reverse of a spontaneously occurring reaction.

The examples which follow will illustrate these general rules.

Examples of electrolysis

1. Molten lead bromide with inert electrodes

This experiment illustrates an electrolysis of no industrial importance, but one which provides a good introduction to the theory of electrolysis because the

results can be interpreted unambiguously. It is best shown as a lecture demonstration, preferably in a fume cupboard, because of the poisonous nature of the lead bromide fumes and bromine vapour (see Appendix II). Routine eye protection is recommended.

About 5 g dry powdered lead(II) bromide is placed in a porcelain 'boat' or crucible, supported on a drilled asbestos board. Two carbon electrodes, fixed in holes in a wooden bar, are clamped in place, touching the compound at points 1 to 3 cm apart (Fig. 1.4). The d.c. supply (about 12 to 20 V) with a rheostat and lamp in series, is switched on. No current passes.

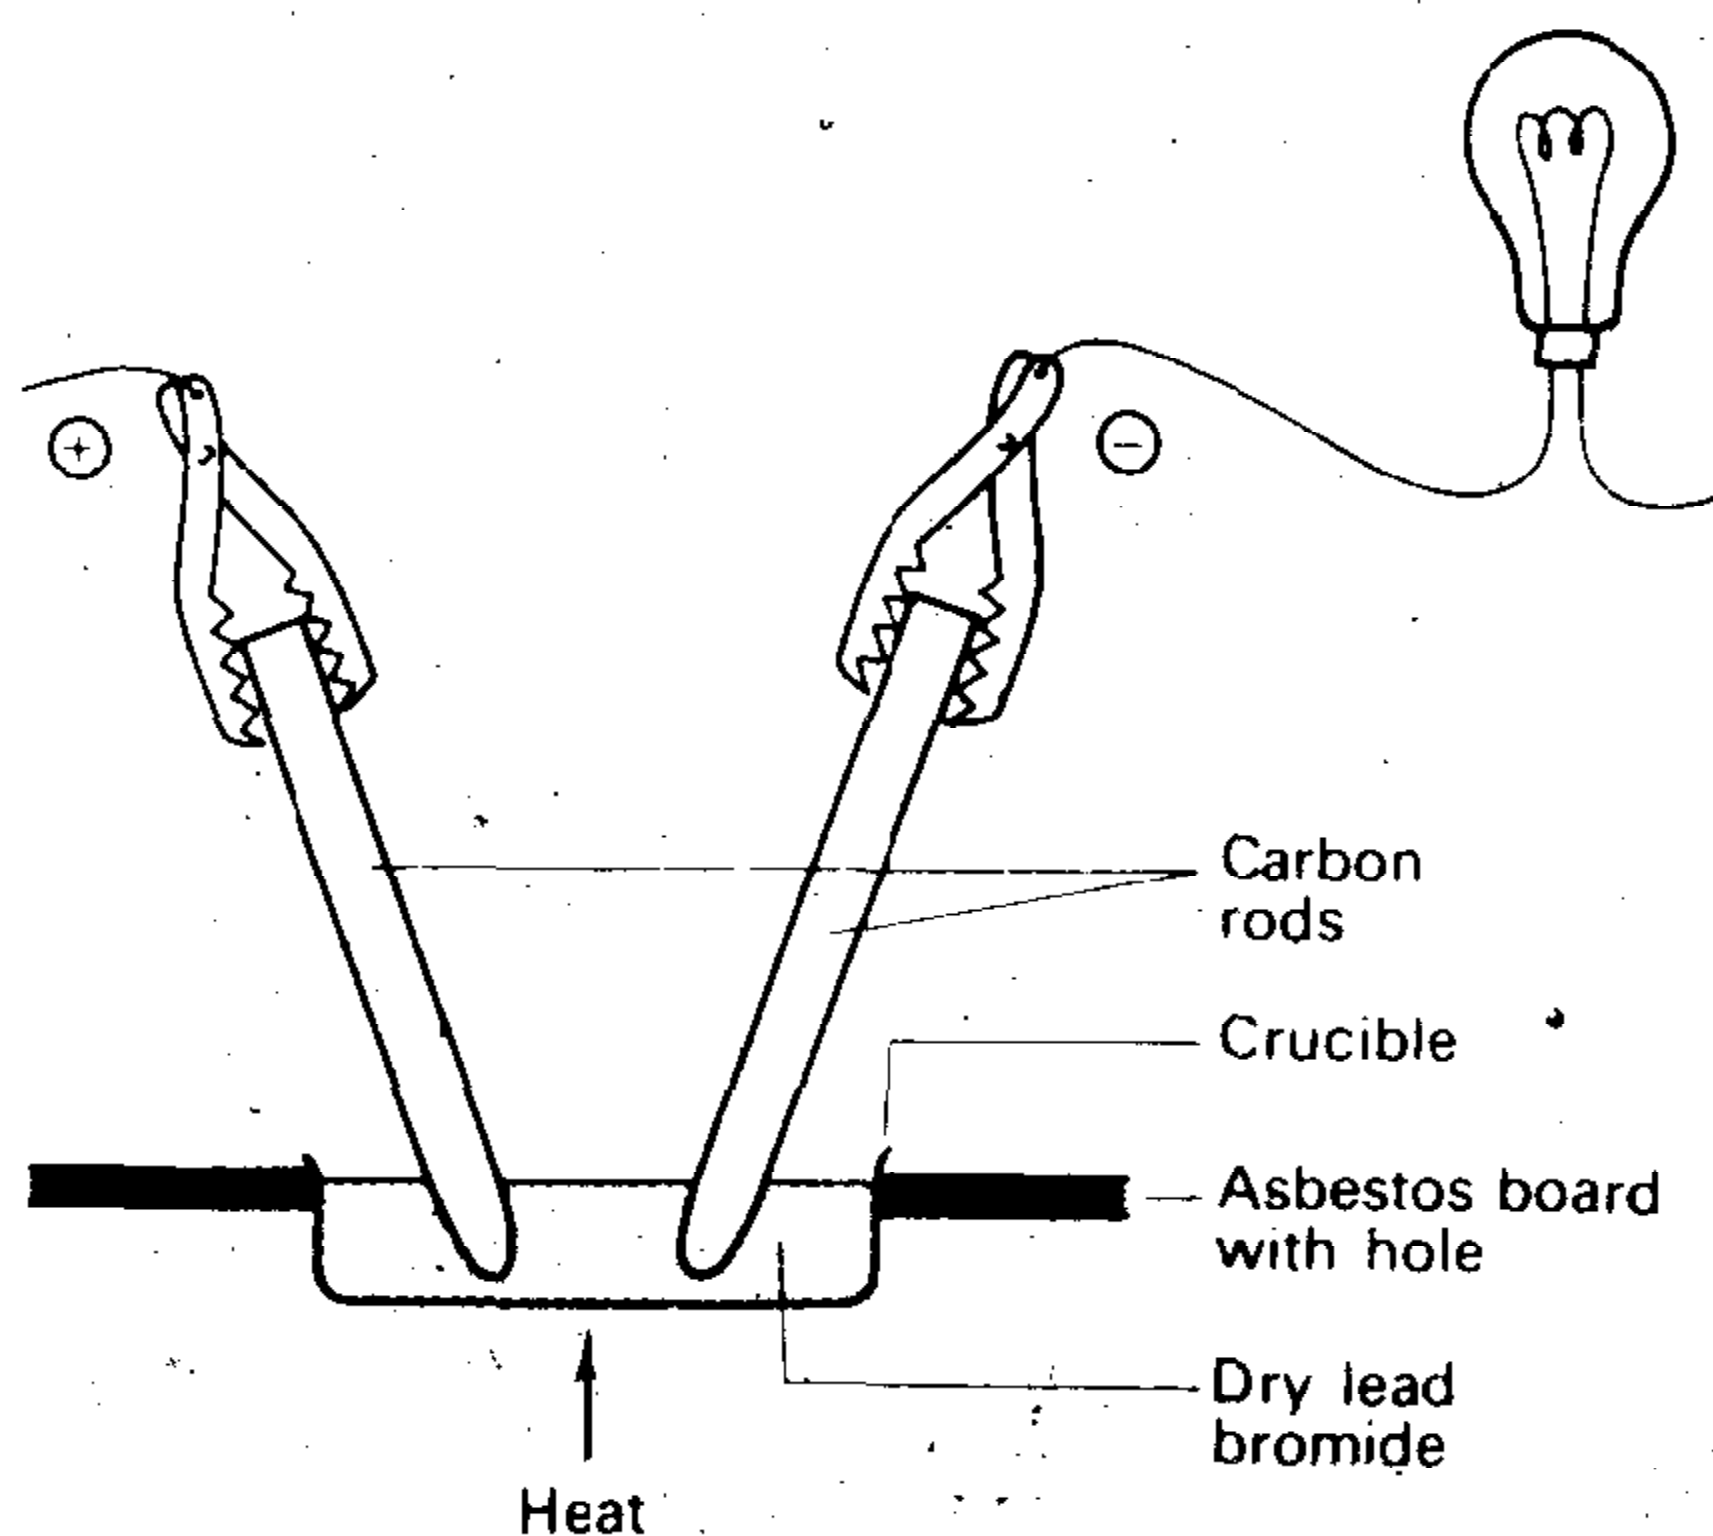

Fig. 1.4   Electrolysis of molten lead bromide

The crucible is heated with a bunsen flame; suddenly the lead bromide melts, and the lamp lights up. After this the heating effect of the current is often sufficient to keep the electrolyte molten. To confirm the point that solid lead bromide does not conduct even when in one piece, with good contact with the electrodes, the current is switched off until the melt solidifies, and then switched on again, no current passes until the solid is remelted.

The current is left on for 5 to 10 minutes. Brown fumes of bromine gas are seen at the positive electrode, and may be tested with starch-iodide paper. Silvery globules of molten lead may sometimes be seen during the electrolysis, but in any case the lead is easily found, after cooling, by dissolving away the residual lead bromide in boiling water.

Assuming that, since they appear to be unchanged, the carbon electrodes do not react, there is only one possible pair of electrode reactions:

At positive anode: Br^- ions arrive and are discharged: $2Br^- \rightarrow Br_2 + 2e^-$

At negative cathode: Pb^{2+} ions arrive and are discharged: $Pb^{2+} + 2e^- \rightarrow Pb$
